Abstract

Exclusive ρ^0 electroproduction at HERA has been studied with the ZEUS detector using 120 pb^{-1} of integrated luminosity collected during 1996–2000. The analysis was carried out in the kinematic range of photon virtuality $2 < Q^2 < 160$ GeV^2, and $\gamma^* p$ centre-of-mass energy $32 < W < 180$ GeV. The results include the Q^2 and W dependences of the $\gamma^* p \to \rho^0 p$ cross section and the decay angular distributions of the ρ^0 meson in the helicity frame. The helicity analysis of the decay-matrix elements of the ρ^0 was used to study the nature of the $\gamma^* p$ cross section for longitudinal and transverse photon as a function of Q^2 and W. Finally, an effective Pomeron trajectory was extracted. The results are compared to various theoretical predictions.

PACS Codes: 13.60.Hb, 13.60.Le

1 Introduction

Two of the most surprising aspects of high-energy deep inelastic scattering (DIS) observed at the HERA ep collider have been the sharp rise of the proton structure function, F_2, with decreasing value of Bjorken x and the abundance of events with a large rapidity gap in the hadronic final state [1]. The latter are identified as due to diffraction in the deep inelastic regime. A contribution to the diffractive cross section arises from the exclusive production of vector mesons (VM).

High-energy exclusive VM production in DIS has been postulated to proceed through two-gluon exchange [2,3], once the scale, usually taken as the virtuality Q^2 of the exchanged photon, is large enough for perturbative Quantum Chromodynamics (pQCD) to be applicable. The gluons in the proton, which lie at the origin of the sharp increase of F_2, are also expected to cause the VM cross section to increase with increasing photon proton centre-of-mass energy, W, with the rate of increase growing with Q^2. Moreover, the effective size of the virtual photon decreases with increasing Q^2, leading to a flatter distribution in t, the four-momentum-transfer squared at

the proton vertex. All these features, with varying levels of significance, have been observed at HERA [4-10] in the exclusive production of ρ^0, ω, ϕ and J/ψ mesons.

This paper reports on an extensive study of the properties of exclusive ρ^0-meson production,

$$\gamma p \to \rho^0 p,$$

based on a high statistics data sample collected with the ZEUS detector during the period 1996–2000, corresponding to an integrated luminosity of about 120 pb^{-1}.

2 Theoretical background

Calculations of the VM production cross section in DIS require knowledge of the $q\bar{q}$ wave-functions of the virtual photon, specified by QED and which depends on the polarisation of the virtual photon. For longitudinally polarised photons, γ^*_L, $q\bar{q}$ pairs of small transverse size dominate [11]. The opposite holds for transversely polarised photons, γ^*_T, where $q\bar{q}$ configurations with large transverse size dominate. The favourable feature of exclusive VM production is that, at high Q^2, the longitudinal component of the virtual photon is dominant. The interaction cross section in this case can be fully calculated in pQCD [11], with two-gluon exchange as the leading process in the high-energy regime. For heavy vector mesons, such as the J/ψ or the Υ, perturbative calculations apply even at $Q^2 = 0$, as the smallness of the $q\bar{q}$ dipole originating from the photon is guaranteed by the mass of the quarks.

Irrespective of particular calculations [12], in the region dominated by perturbative QCD the following features are predicted:

- the total $\gamma^* p \to Vp$ cross section, $\sigma_{\gamma^* p}$, exhibits a steep rise with W, which can be parameterised as $\sigma \sim W^\delta$, with δ increasing with Q^2;

- the Q^2 dependence of the cross-section, which for a longitudinally polarised photon is expected to behave as Q^{-6}, is moderated to become Q^{-4} by the rapid increase of the gluon density with Q^2;

- the distribution of t becomes universal, with little or no dependence on W or Q^2;

- breaking of the s-channel helicity conservation (SCHC) is expected.

In the region where perturbative calculations are applicable, exclusive vector-meson production could become a complementary source of information on the gluon content of the proton. At present, the following theoretical uncertainties have been identified:

• the calculation of $\sigma(\gamma^* p \to Vp)$ involves the generalised parton distributions [8,13,14], which are not well tested in addition [15], it involves gluon densities outside the range constrained by global QCD analyses of parton densities;

• higher-order corrections have not been fully calculated [14]; therefore the overall normalisation is uncertain and the scale at which the gluons are probed is not known;

• the rapid rise of $\sigma_{\gamma^* p}$ with W implies a non-zero real part of the scattering amplitude, which is not known;

• the wave-functions of the vector mesons are not fully known.

In spite of all these problems, precise measurements of differential cross sections separated into longitudinal and transverse components [17], should help to resolve the above theoretical uncertainties.

It is important in these studies to establish a region of phase space where hard interactions dominate over the non-perturbative soft component. If the relative transverse momentum of the $q\bar{q}$ pair is small, the colour dipole is large and perturbative calculations do not apply. In this case the interaction looks similar to hadron-hadron elastic scattering, described by soft Pomeron exchange as in Regge phenomenology [18].

The parameters of the soft Pomeron are known from measurements of total cross sections for hadron-hadron interactions and elastic proton-proton measurements. It is usually assumed that the Pomeron trajectory is linear in t:

$$\alpha_{\mathbb{P}}(t) = \alpha_{\mathbb{P}}(0) + \alpha'_{\mathbb{P}} t. \tag{1}$$

The parameter $\alpha_{\mathbb{P}}(0)$ determines the energy behaviour of the total cross section,

$$\sigma_{tot} \sim (W^2)^{\alpha_{\mathbb{P}}(0)-1}$$

and $\alpha'_{\mathbb{P}}$ describes the increase of the slope b of the t distribution with increasing W. The value of $\alpha'_{\mathbb{P}}$ is inversely proportional to the square of the typical transverse momenta participating in the

exchanged trajectory. A large value of $\alpha'_{\mathbb{P}}$ suggests the presence of low transverse momenta typical of soft interactions. The accepted values of $\alpha_{\mathbb{P}}(0)$ [19] and $\alpha'_{\mathbb{P}}$ [20] are

$$\alpha_{\mathbb{P}}(0) = 1.096 \pm 0.003$$
$$\alpha'_{\mathbb{P}} = 0.25\ \mathrm{GeV}^{-2}.$$

The non-universality of $\alpha_{\mathbb{P}}(0)$ has been established in inclusive DIS, where the slope of the $\gamma^* p$ total cross section with W has a pronounced Q^2 dependence [21]. The value of $\alpha'_{\mathbb{P}}$ can be determined from exclusive VM production at HERA via the W dependence of the exponential b slope of the t distribution for fixed values of W, where b is expected to behave as

$$b(W) = b_0 + 4\alpha'_{\mathbb{P}} \ln \frac{W}{W_0},$$

where b_0 and W_0 are free parameters. The value of $\alpha'_{\mathbb{P}}$ can also be derived from the W dependence of $d\sigma/dt$ at fixed t,

$$\frac{d\sigma}{dt}(W) = F(t) W^{4(\alpha_{\mathbb{P}}(t)-1)}, \tag{2}$$

where $F(t)$ is an arbitrary function. This approach has the advantage that no assumption needs to be made about the t dependence. The first indications from measurements of $\alpha_{\mathbb{P}}(t)$ in exclusive J/ψ photoproduction [8,22] are that $\alpha_{\mathbb{P}}(t)$ is larger and $\alpha'_{\mathbb{P}}$ is smaller than those of the above soft Pomeron trajectory.

2 Experimental set-up

The present measurement is based on data taken with the ZEUS detector during two running periods of the HERA ep collider. During 1996–1997, protons with energy 820 GeV collided with 27.5 GeV positrons, while during 1998–2000, 920 GeV protons collided with 27.5 GeV electrons or positrons. The sample used for this study corresponds to an integrated luminosity of 118.9 pb^{-1}, consisting of 37.2 pb^{-1} of e^+p sample from 1996–1997 and 81.7 pb^{-1} from the 1998–2000 sample (16.7 pb^{-1} and 65.0 pb^{-1} e^-p)[1].

A detailed description of the ZEUS detector can be found elsewhere [23,24]. A brief outline of the components that are most relevant for this analysis is given below.

1. From now on, the word "electron" will be used as a generic term for both electrons and positrons.

Charged particles are tracked in the central tracking detector (CTD) [25-27]. The CTD consists of 72 cylindrical drift chamber layers, organized in nine superlayers covering the polar-angle [1] region $15° < \theta < 164°$. The CTD operates in a magnetic field of 1.43 T provided by a thin solenoid. The transverse-momentum resolution for full-length tracks is $\sigma(p_T)/p_T = 0.0058p_T \oplus 0.0065 \oplus 0.0014/p_T$, with p_T in GeV.

The high-resolution uranium-scintillator calorimeter (CAL) [28-31] covers 99.7% of the total solid angle and consists of three parts: the forward (FCAL), the barrel (BCAL) and the rear (RCAL) calorimeters. Each part is subdivided transversely into towers and longitudinally into one electromagnetic section (EMC) and either one (in RCAL) or two (in BCAL and FCAL) hadronic sections. The CAL energy resolutions, as measured under test-beam conditions, are $\sigma(E)/E = 0.18/\sqrt{E}$ for electrons and $\sigma(E)/E = 0.35/\sqrt{E}$ for hadrons, with E in GeV.

The position of the scattered electron was determined by combining information from the CAL, the small-angle rear tracking detector [32] and the hadron-electron separator [33].

In 1998, the forward plug calorimeter (FPC) [34] was installed in the $20 \times 20\ \text{cm}^2$ beam hole of the FCAL with a small hole of radius 3.15 cm in the centre to accommodate the beam pipe. The FPC increased the forward calorimeter coverage by about one unit in pseudorapidity to $\eta \leq 5$.

The leading-proton spectrometer (LPS) [35] detected positively charged particles scattered at small angles and carrying a substantial fraction, x_L, of the incoming proton momentum; these particles remained in the beam-pipe and their trajectories were measured by a system of silicon microstrip detectors, located between 23.8 m and 90.0 m from the interaction point. The particle deflection induced by the magnets of the proton beam-line allowed a momentum analysis of the scattered proton.

During the 1996–1997 data taking, a proton-remnant tagger (PRT) was used to tag events in which the proton dissociates. It consisted of two layers of scintillation counters perpendicular to the beam at $z = 5.15$ m. The two layers were separated by a 2 mm-thick lead absorber. The pseudorapidity range covered by the PRT was $4.3 < \eta < 5.8$.

The luminosity was measured from the rate of the bremsstrahlung process $ep \to ep\gamma$. The photon was measured in a lead-scintillator calorimeter [36-38] placed in the HERA tunnel at $z = -107$ m.

1 The OEDA coordinate system is a right-handed Cartesian system, with the Z axis pointing in the proton direction, referred to as the "forward direction", and the X axis pointing left towards the centre of HERA. The coordinate origin is at the nominal interaction point.

4 Data selection and reconstruction

The following kinematic variables are used to describe exclusive ρ^0 production and its subsequent decay into a $\pi^+\pi^-$ pair:

- the four-momenta of the incident electron (k), scattered electron (k'), incident proton (P), scattered proton (P') and virtual photon (q);

- $Q^2 = -q^2 = -(k - k')^2$, the negative squared four-momentum of the virtual photon;

- $W^2 = (q + P)^2$, the squared centre-of-mass energy of the photon-proton system;

- $y = (P \cdot q)/(P \cdot k)$, the fraction of the electron energy transferred to the proton i n its rest frame;

- $M_{\pi\pi}$, the invariant mass of the two decay pions;

- $t = (P - P')^2$, the squared four-momentum transfer at the proton vertex;

- three helicity angles, Φ_h, θ_h^* and ϕ_h (see Section 9).

The kinematic variables were reconstructed using the so-called "constrained" method [10,39], which uses the momenta of the decay particles measured in the CTD and the reconstructed polar and azimuthal angles of the scattered electron.

The online event selection required an electron candidate in the CAL, along with the detection of at least one and not more than six tracks in the CTD.

In the offline selection, the following further requirements were imposed:

- the presence of a scattered electron, with energy in the CAL greater than 10 GeV and with an impact point on the face of the RCAL outside a rectangular area of $26.4 \times 16\ cm^2$;

- $E - P_Z \approx 45$ GeV, where $E - P_Z = \sum_i (E_i - P_{Z,i})$ and the summation is over the energies and longitudinal momenta of the final-state electron and pions, was imposed. This cut excludes events with high-energy photons radiated in the initial state;

- the Z-coordinate of the interaction vertex within ± 50 cm of the nominal interaction point;

- in addition to the scattered electron, exactly two oppositely charged tracks, each associated with the reconstructed vertex, and each having pseudorapidity $|\eta|$ less than 1.75 and transverse

momentum greater than 150 MeV; this excluded regions of low reconstruction efficiency and poor momentum resolution in the CTD. Those tracks were treated in the following analysis as a $\pi^-\pi^+$ pair.

• events with any energy deposit larger than 300 MeV in the CAL and not associated with the pion tracks (so-called 'unmatched islands') were rejected [40-42].

In addition, the following requirements were applied to select kinematic regions of high acceptance:

• the analysis was restricted to the kinematic regions 2 <Q^2< 80 GeV^2 and 32 <W< 160 GeV in the 1996–1997 data and 2 <Q^2< 160 GeV^2 and 32 <W< 180 GeV in the 1998–2000 sample;

• only events in the $\pi^-\pi^+$ mass interval 0.65 <$M_{\pi\pi}$< 1.1 GeV and with $|t|$ < 1 GeV^2 were taken. The mass interval is slightly narrower than that used previously [10], in order to reduce the effect of the background from non-resonant $\pi^-\pi^+$ production. In the selected $M_{\pi\pi}$ range, the resonant contribution is ~ 100% (see Section 8).

The above selection yielded 22,400 events in the 1996–1997 sample and 49,300 events in the 1998–2000 sample, giving a total of 71,700 events for this analysis.

5 Monte Carlo simulation

The relevant Monte Carlo (MC) generators have been described in detail previously [10]. Here their main features are summarised.

The program ZEUSVM [43] interfaced to HERACLES4.6 [44] was used. The effective Q^2, W and t dependences of the cross section were parameterised to reproduce the data [42].

The decay angular distributions were generated uniformly and the MC events were then iteratively reweighted using the results of the present analysis for the 15 combinations of matrix elements r^{04}_{ik}, r^1_{ik} (see Section 9).

The contribution of the proton-dissociative process was studied with the EPSOFT [45] generator for the 1996–1997 data and with PYTHIA [46] for the 1998–2000 data. The Q^2, W and t dependences were parameterised to reproduce the control samples in the data. The decay angular distributions were generated as in the ZEUSVM sample.

The generated events were processed through the same chain of selection and reconstruction procedures as the data, thus accounting for trigger as well as detector acceptance and smearing effects. For both MC sets, the number of simulated events after reconstruction was about a factor of seven greater than the number of reconstructed data events.

All measured distributions are well described by the MC simulations. Some examples are shown in Fig. 1, for the W, Q^2, z variables, and the three helicity angles, θ_h, ϕ_h and Φ_h, and in Fig. 2 for the transverse momentum p_T of the pion, for different Q^2 bins.

6 Systematics

The systematic uncertainties of the cross section were evaluated by varying the selection cuts and the MC simulation parameters. The following selection cuts were varied:

- the $E - P_z$ cut was changed within the appropriate resolution of ± 3 GeV;
- the y_h of the pion tracks (default 0.15 GeV) was increased to 0.2 GeV;
- the distance of closest approach of the extrapolated track to the matched island in the CAL was changed from 30 cm to 20 cm;

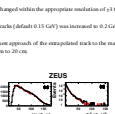

Figure 1
Comparison between the data and the ZEUS-SYNTHESIS distributions for (a) W, (b) Q^2, (c) $|t|$, (d) $\cos\theta_h$, (e) ϕ_h and (f) Φ_h for events with $5.0 < W < 1.1$ GeV and $Q^2 < 1.0$ GeV^2. The MC distributions are normalised to the data.

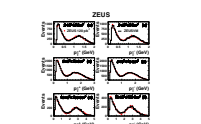

Figure 2
Comparison between the data and the ZEUSVM MC distributions for the transverse momenta p_T of e^+ and π^+ particles, for different ranges of Q^2, as indicated in the figure. The errors are calculated as in within ICAS: $\sqrt{N_{data}}$ + 1 GeV and $\sqrt{N}$ - 1 GeV. The MC distributions are normalised to the data.

- the E-p_z-max window was changed to 0.65–1.2 GeV;
- the Z vertex cut was varied by ±10 cm;
- the rectangular area of the electron impact point on the CAL was increased by 0.5 cm in X and Y;
- the energy of an unmatched island was lowered to 0.25 GeV and then raised to 0.35 GeV.

The dependence of the results on the precision with which the MC reproduces the performance of the detector and the data was checked by varying the following inputs within their estimated uncertainty:

- the reconstructed position of the electron was shifted with respect to the MC by ±1 mm;
- the electron-position resolution was varied by ±10% in the MC;
- the W^2-dependence in the MC was changed by varying β by ±0.03;

• the exponential *t*-distribution in the MC was reweighted by changing the nominal slope parameter *b* by $\pm 5\ GeV^{-2}$;

• the angular distributions in the MC were reweighted assuming SCHC;

• the Q^2-distribution in the MC was reweighted by $(Q^2 + M_{J/\psi}^2)^n$, where $n = \pm 0.05$.

The largest uncertainty of about ±8% originated from the variation of the energy of the unmatched islands. All the other checks resulted on average in a ±0.5% change in the measured cross sections. All the systematic uncertainties were added in quadrature. In addition, the cross-section measurements have an overall normalisation uncertainty of ±2% due to the luminosity measurement.

7 Proton dissociation

The production of J/ψ mesons may be accompanied by the proton-dissociation process, $\gamma^* p \to J/\psi N$, for low masses M_X of the dissociative system N; the hadronisation products may remain inside the beam-pipe, leaving no signals in the main detector. The contribution of these events to the exclusive J/ψ cross section was estimated from MC generators for proton-dissociative processes.

A class of proton dissociative events for which the final-state particles leave observed signals in the surrounding detectors was used to tune the M_X and the t distribution in the MC. In the 1998–2000 running period, those events were selected by requiring a signal in the FPC detector with energy above 1 GeV. The comparison of the data with PYTHIA expectations for the energy distribution in the FPC is shown in Fig. 3(a). The same procedure was repeated with a sample of J/ψ events for which the FPC energy was less than 1 GeV and a leading proton was measured in the LPS detector, with the fraction of the incoming proton momentum $x_L < 0.95$. The comparison between the t distribution measured in the data and that expected from PYTHIA is shown in Fig. 3(b), where the elastic peak in the data ($x_L > 0.95$) is also observed. Also shown in Fig. 3(c)–(e) is the fraction of proton-dissociative events expected in the selected J/ψ sample as a function of Q^2, W and z. The fraction is at the level of 19% independent of Q^2 and W, but increasing with z. Assuming [6], The combined use of the FPC and LPS methods was used to estimate of the proton dissociative contribution for $|z < 1\ GeV^2$ of $0.19 \pm 0.02(\text{stat.}) \pm 0.01(\text{syst.})$. The systematic uncertainty was estimated by varying the parameters of the M_X-distribution and by changing the FPC cut.

In the 1996–1997 data-taking period, a similar procedure was applied, after tuning the EPSOM MC to reproduce events with hits in the PRT or energy deposits in the FCAL. The proton-dissociative contribution for $|z < 1\ GeV^2$ was determined to be 0.07 ± 0.02 after rejecting

Figure 4
The $\pi^+\pi^-$ mass spectrum corrected for detector acceptance, efficiency and resolution effects. The line represents the best fit of the Söding form to the data in the range $0.44 < M_{\pi^+\pi^-} < 1.1$ GeV. The vertical lines indicate the range of masses used for the analysis. The dashed line is the shape of a relativistic Breit-Wigner with the fitted parameters given in the figure. The dotted line is the interference term between the non-resonant background (dash-dotted line) and the ρ^0 signal.

In order to estimate the non-resonant $\pi^+\pi^-$ background under the ρ^0, the Söding parameterisation [47] was fitted to the data, with results shown in the figure. The resulting mass and width values are in agreement with those given in the Particle Data Group [48] compilation. The integrated non-resonant background is of the order of 1% and is thus neglected.

The $\pi^+\pi^-$ mass distributions in different regions of Q^2 and z are shown in Fig. 5 and Fig. 6, respectively. The shape of the mass distribution changes neither with Q^2 nor with z. The results of the fit to the Söding parameterisation are also shown. Note that the interference term decreases with Q^2 as expected but is independent of z, indicating that the non-exclusive background is negligible.

Angular distributions and decay-matrix density

The exclusive electroproduction and decay of ρ^0 mesons is described, at fixed W, Q^2, $M_{\pi\pi}$ and t, by three helicity angles: Φ_h is the angle between the ρ^0 production plane and the electron scattering plane in the $\gamma^* p$ centre-of-mass frame; θ_h and ϕ_h are the polar and azimuthal angles of the positively charged decay pion in the ρ^0 helicity frame. In this frame, the spin-quantisation axis is defined as the direction opposite to the momentum of the final-state proton in the ρ^0 rest frame. In the $\gamma^* p$ centre-of-mass system, ϕ_h is the angle between the decay plane and the ρ^0 pro-

duction plane. The angular distribution as a function of these three angles, $W(\cos\theta_V, \phi_V, \Phi_V)$, is parameterised by the ρ^0-spin-density matrix elements, ρ^0_{kl}, where $l, k = 1, 0, 1$ and by convention $\alpha = 0, 1, 2, 4, 5, 6$ for an unpolarised charged-lepton beam [49]. The superscript denotes the decomposition of the spin-density matrix into contributions from the following photon-polarisation states: unpolarised transverse photons (0); linearly polarised transverse photons ($1, 2$); longitudinally polarised photons (4); and from the interference of the longitudinal and transverse amplitudes ($5, 6$).

The decay angular distribution can be expressed in terms of combinations, r^α_{04} and r^α_{1l} of the density matrix elements

$$r^\alpha_{04} = \begin{cases} \frac{\rho^0_{00}+\varepsilon R\rho^0_{11}}{1+\varepsilon R}, & \alpha = 1, 2 \\ \frac{\rho^0_{00}-\rho^0_{11}}{1+\varepsilon R}, & \\ \frac{\sqrt{R}\rho^0_{10}}{1+\varepsilon R}, & \alpha = 5, 6, \end{cases}$$

where ε is the ratio of the longitudinal- to transverse-photon fluxes and $R = \sigma_L/\sigma_T$, with σ_L and σ_T the cross sections for exclusive ρ^0 production from longitudinal and transverse virtual photons, respectively. In the kinematic range of this analysis, the value of ε varies between 0.96 and 1 with an average value of 0.996; hence ρ^0_{00} and ρ^0_{11} cannot be distinguished.

The Hermitian nature of the spin-density matrix and the requirement of parity conservation reduces the number of independent parameters to 15 [49]. A 15-parameter fit was performed to the data and the obtained results are listed in Table 1 and shown in Fig. 7 as a function of Q^2. The published ZEUS results [50] at lower Q^2 values and the expectations of SCHC, when relevant, are also included. The observed Q^2 dependence, expected in some calculations [51] and previously reported by H1 [52], is driven by the R dependence on Q^2 under the assumption of helicity conservation and natural parity exchange. The significant deviation of r^1_{00} from zero shows that SCHC does not hold [51] as was observed previously [50,52].

The angular distribution for the decay of the ρ^0 meson, integrated over ϕ_V and Φ_V, reduces to

$$W(\cos\theta_h) = \left(1 - r_{00}^{04}\right) + \left(3r_{00}^{04} - 1\right)\cos^2\theta_h \quad (3)$$

The element r_{00}^{04} may be extracted from a one-dimensional fit to the $\cos\theta_h$ distribution. The $\cos\theta_h$ distributions, for different Q^2 intervals, are shown in Fig. 8, together with the results of a one-dimensional fit of the form (3). The data are well described by the fitted parameter r_{00}^{04} at each value of Q^2.

10 Cross section

The measured $\gamma^* p$ cross sections are averaged over intervals listed in the appropriate tables and are quoted at fixed values of Q^2 and W. The cross sections are corrected for the mass range $0.28 \leq M_{\pi\pi} < 1.5$ GeV and integrated over the full-range, where applicable.

Figure 7
The 13 density-matrix elements, obtained from a fit to the data (dots), as a function of Q^2. Also shown in the figure are the SCHC predictions (horizontal dashed lines, where existing). The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature. The dashed line at zero is the expectation from SCHC when relevant.

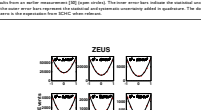

Figure 8
The acoplanar-corrected $\cos\theta_h$ distribution, for different Q^2 intervals, with mean values indicated in the figure. The line represents the fit to the data of Eq. (5).

18.1 t dependence of σ(ℓ⁺p → ℓ⁺γp)

The determination of $d\sigma/dt\,(\ell^+p \to \ell^+p\gamma)$ as a function of t for $W = 90$ GeV was performed by averaging over $40 < W < 140$ GeV. The differential cross-section $d\sigma/dt\,(\ell^+p \to \ell^+p\gamma)$ is shown in Fig. 9 and listed in Table 2, for different ranges of Q^2. An exponential form proportional to e^{Bt} was fitted to the data in each range of Q^2; the results are shown in Fig. 10. The exponent b, listed in Table 3, decreases as a function of Q^2. After including the previous results at lower Q^2 [14,15], a sharp decrease of b is observed at low Q^2; the value of b then levels off at about 5 GeV^{-2}.

A compilation of the value of the slope b for exclusive VM electroproduction, as a function of $Q^2 + M^2$, is shown in Fig. 11. Here M is the mass of the corresponding final state. It also includes the exclusive production of a real photon, the deeply virtual Compton scattering (DVCS) measurement [34]. When b is plotted as a function of $Q^2 + M^2$, the trend of b decreasing with increasing scale to an asymptotic value of 5 GeV^{-2}, seems to be a universal property of exclusive processes, as expected in perturbative QCD [2].

18.2 Q^2 dependence of σ(ℓ⁺p → ℓ⁺γp)

The determination of $d\sigma/dt\,(\ell^+p \to \ell^+p\gamma)$ as a function of Q^2 for $W = 90$ GeV was performed by averaging over $40 < W < 140$ GeV. The results are shown in Fig. 12 with corresponding values given

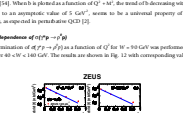

Figure 9
The differential cross-section $d\sigma/dt$ for $e^+p \to e^+p\gamma$ for fixed values of Q^2, as indicated in the figure. The line represents an exponential fit to the data. The inner error bars indicate the statistical uncertainty; the outer error bars represent the statistical and systematic uncertainty added in quadrature.

Table 2: The differential cross section $d\sigma/dx$ for the reaction $\gamma p \to \rho^0 p$ for different Q^2 intervals. The first column gives the Q^2 bin, while the second column gives the Q^2 value at which the cross section is quoted. The normalization uncertainty due to luminosity (6.3%) and proton dissociation background (4–6%), is not included.

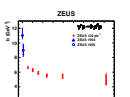

Figure 10
The value of the slope b from a fit of the form $d\sigma/dx|_{t=0} \sim x^{-4(b-1)}$ for exclusive J/ψ electroproduction, as a function of Q^2. Also shown are values of b obtained previously at lower Q^2 values [18, 33]. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

Table 3: The slope b resulting from a fit to the differential cross-section $d\sigma/dx$ to an exponential form for the scalars $\sigma(\gamma^* \gamma^* p)$ for different Q^2 intervals. The first column gives the Q^2 interval, the second the mean value of Q^2 and the third the differential cross-section per scalar. The first uncertainty is statistical, the second systematic.

Q^2 min (GeV^2)	Q^2 (GeV^2)	b (GeV^{-2})
3.4	3.7	$4.4 \pm 0.5^{+0.5}_{-0.3}$
4.43	5.0	$4.3 \pm 0.2^{+0.2}_{-0.2}$
6.5–10	7.8	$3.9 \pm 0.2^{+0.3}_{-0.2}$
10–15	11.9	$3.5 \pm 0.2^{+0.2}_{-0.2}$
15–35	19.7	$3.5 \pm 0.3^{+0.3}_{-0.2}$
35–80	41.0	$4.0 \pm 0.4^{+0.4}_{-0.3}$

in Table 4. As expected, a steep decrease of the cross section with Q^2 is observed. The photoproduction and the low-Q^2 (< 1 GeV^2) measurements are also shown in the figure. An attempt to fit the Q^2 dependence with a simple propagator term

$$\sigma(\gamma^* p \to \rho^0 p) \propto \left(\hat{Q}^2 + m_\rho^2\right)^{-n},$$

with the normalisation and n as free parameters, failed to produce results with an acceptable χ^2. The data appear to favour a value which increases with Q^2.

10.3 W dependence of $\sigma(\gamma^* p \to \rho^0 p)$

The values of the cross section $\sigma(\gamma^* p \to \rho^0 p)$ as a function of W, for fixed values of Q^2, are plotted in Fig. 11 and given in Table 5. The cross sections increase with increasing W, with the rate of increase growing with increasing Q^2.

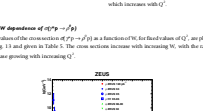

Figure 11
A compilation of the value of the slope b from a fit of the form $d\sigma/dt \propto e^{bt}$ for exclusive vector-meson electroproduction as a function of $Q^2 + M^2$. Also included is the DVCS result. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

II $R = \sigma_L/\sigma_T$ and $c_{ss}^{(n)}$

The SCHC hypothesis implies that $r_{++}^1 = -\tan\frac{\theta}{2}\cdot r_{0+}^1$ and $\mathrm{Re}\{r_{++}^1\} = -\tan\frac{\theta}{2}\cdot r_{0+}^1$. In this case, the ratio $R = \sigma_L/\sigma_T$ can be related to the $c_{ss}^{(n)}$ matrix element,

$$R = 2\frac{c_{00}^{(1)}}{1 - c_{00}^{(0)}} \tag{4}$$

and thus can be extracted from the ϕ_e^* distribution alone.

If the SCHC requirement is relaxed, then the relation between R and $c_{00}^{(n)}$ is modified,

$$R = \frac{1}{\varepsilon}\frac{c_{00}^{(1)} - \sqrt{\varepsilon}}{1 - \left(c_{00}^{(0)} - \sqrt{\varepsilon}\right)}$$

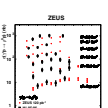

Figure 10

Comparison of the H1 (squares) and ZEUS (dots) measurements of the W dependence of $d\sigma^{\gamma^* p\to J/\psi p}/dW$, for different Q^2 values, as indicated in the figure. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

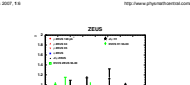

Figure 16
A compilation of the value of β from a fit of the form R^2 for exclusive vector-meson electroproduction, as a function of $Q^2 + M^2$. It includes also the ZEUS results. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

with

$$\Delta = \frac{\sqrt{\Sigma}}{\sum_{ij} \Sigma_{ij}^{-1}}$$

In the kinematic range of the measurement presented in this paper, the non-zero value of Δ implies a correction of ~3% on R up to the highest Q^2 value, where it is ~10%, and is neglected.

Under the assumption that Eq. (4) is valid and the values of σ studied in this paper, $\omega \tau > \sim 0.996$, the matrix element Σ_{ij}^{kl} may be interpreted as

$$\Sigma_{ij}^{kl} = \sigma_i^2 \langle \delta_{ik}^2 \rangle \delta_{jl}^2,$$

where $\sigma_{i,k} = \sigma_i + \sigma_k$. When the value of Σ_{ij}^{kl} is close to one, as is the case for this analysis, the error on R becomes large and highly asymmetrical. It is then advantageous to study the properties of σ_{ij}^{kl} itself which carries the same information, rather than R.

The Q^2 dependence of $\sigma_{tot}^{\gamma p}$ for W = 90 GeV, averaged over the range 40 <W< 140 GeV, is shown in Fig. 17 and listed in Table 7 together with the corresponding R values. The figure includes three data points at lower Q^2 from previous studies [10,33]. An initial steep rise of $\sigma_{tot}^{\gamma p}$ with Q^2 is observed and above $Q^2 \approx 10$ GeV^2, the rise with Q^2 becomes milder. At Q^2 = 40 GeV^2, σ_L constitutes about 50% of the total $\gamma^* p$ cross section.

The comparison of the H1 and ZEUS results is presented in Fig. 18 in terms of the ratio R. The H1 measurements are at W = 75 GeV and those of ZEUS at W = 90 GeV. Given the fact that R seems to be independent of W (see below), both data sets can be directly compared. The two measurements are in good agreement.

The dependence of R on $M_{\rho\pi}$ is presented in Fig. 19 for two Q^2 intervals. The value of R falls rapidly with $M_{\rho\pi}$ above the central ρ^0 mass value. Although a change of R with $M_{\rho\pi}$ was anticipated to be ~ 10% [55], the effect seen in the data is much stronger. The effect remains strong also at higher Q^2, contrary to expectations [55]. Once averaged over the ρ^0 mass region, the main contribution to R comes from the central ρ^0 mass value.

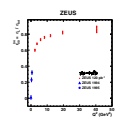

Figure 17
The ratio $\sigma_{tot}^{\gamma p}$ as a function of Q^2 for W = 90 GeV. Also included are values of $\sigma_{tot}^{\gamma p}$ from previous measurements at lower Q^2 values [10, 33]. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

Table 7: The spin-matrix element r_{00}^{04} and the ratio of cross-sections for longitudinally and transversely polarised photons, $R = \sigma_L/\sigma_T$, as a function of Q^2, averaged over the Q^2 and W bins given in the table. The first uncertainty is statistical, the second systematic.

Q^2 low (GeV^2)	Q^2 (GeV^2)	W bin (GeV)	r_{00}^{04}	$R = \sigma_L/\sigma_T$
2–3	2.4	32–120	$0.48 \pm 0.01^{+0.03}_{-0.04}$	$1.08^{+0.05+0.08}_{-0.05-0.07}$
3–5	3.7	32–120	$0.48 \pm 0.01^{+0.03}_{-0.04}$	$1.10^{+0.05+0.08}_{-0.05-0.07}$
5–7	5.9	40–140	$0.73 \pm 0.02^{+0.03}_{-0.04}$	$2.75^{+0.17+0.22}_{-0.13-0.20}$
7–10	8.3	40–140	$0.74 \pm 0.02^{+0.03}_{-0.04}$	$2.92^{+0.19+0.23}_{-0.14-0.21}$
10–15	12.0	40–140	$0.79 \pm 0.03^{+0.03}_{-0.04}$	$3.92^{+0.34+0.32}_{-0.24-0.29}$
15–35	19.5	40–140	$0.82 \pm 0.02^{+0.03}_{-0.04}$	$4.65^{+0.32+0.37}_{-0.23-0.34}$
35–100	48.5	40–140	$0.86 \pm 0.04^{+0.03}_{-0.04}$	$6.10^{+0.76+0.49}_{-0.52-0.45}$

The W dependence of r_{00}^{04}, for different values of Q^2, is shown in Fig. 20 and listed in Table 8. Within the measurement uncertainties, r_{00}^{04} is independent of W, for all Q^2 values. This implies that the W behaviour of σ_L is the same as that of σ_T, a result which is somewhat surprising. The

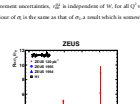

Figure 19
The ratio of the H1 (squares) and ZEUS (dots) measurements of R as a function of Q^2. The H1 data are at W = 75 GeV and those of ZEUS at W = 90 GeV. Also included are measurements performed previously at lower Q^2 values [35, 55]. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

Figure 19
The value of α_s as a function of $M_{c,pole}$ for $W = 80$ GeV, and for two values of Q^2, as indicated in the figure. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

Figure 20
The ratio $\frac{\sigma_{cc}^{vis}}{\sigma_{bb}^{vis}}$ as a function of W for different values of Q^2, as indicated in the figure. The inner error bars indicate the statistical uncertainty, the outer error bars represent the statistical and systematic uncertainty added in quadrature.

Table 6: The spin-matrix element $\frac{dG_M}{dQ^2}$ and the ratio of cross sections for longitudinally and transversely polarized photons, $R_T \equiv 2\sigma_T/\sigma_L$, as a function of W for different values of Q^2, averaged over the $\frac{3^+}{2}$ and $\frac{5^+}{2}$ resonances in the table. The first uncertainty is statistical, the second systematic.

Q^2 (GeV/c)^2	$\frac{dG_M}{dQ^2}$ (GeV/c)$^{-2}$	W bin (GeV)	W (GeV)	$\frac{dG_M}{dQ^2}$	$R_T \equiv 2\sigma_T/\sigma_L$
2–3	2–4	32–55	4.0	$0.440 \pm 0.047^{+0.055}_{-0.055}$	$1.39^{+0.55}_{-0.55} \pm 0.55$

7–13	8–8	70–100	8.5	$0.76 \pm 0.07^{+0.10}_{-0.10}$	$3.17^{+1.24}_{-1.24} \pm 1.24$
7–13	8–8	100–140	7.20	$0.76 \pm 0.07^{+0.10}_{-0.10}$	$3.17^{+1.24}_{-1.24} \pm 1.24$
13–30	18–9	50–90	5.5	$0.99 \pm 0.09^{+0.13}_{-0.13}$	$5.29^{+2.08}_{-2.08} \pm 2.08$
13–30	18–9	70–130	8.5	$0.83 \pm 0.08^{+0.11}_{-0.11}$	$4.54^{+1.78}_{-1.78} \pm 1.78$
13–30	18–9	130–140	1.30	$0.83 \pm 0.08^{+0.11}_{-0.11}$	$4.66^{+1.83}_{-1.83} \pm 1.83$

$\frac{3^+}{2}$ configurations in the wave function of γ_v^* have typically a small transverse size, while the configurations contributing to γ_v^* may have large transverse size. The contribution to σ_L of large-size $\frac{3^+}{2}$ configurations, which are more hadron-like, is expected to lead to a shallower W dependence than in case of σ_T. Thus, the result presented in Fig. 20 suggests that the large-size configurations of the transversely polarized photon are suppressed.

The above conclusion can also explain the behaviour of $\frac{dG_M}{dQ^2}$ as a function of τ, shown in Fig. 21 and presented in Table 9 for two Q^2 values. Different sizes of interacting objects imply different τ distributions, in particular a steeper $d\sigma_L/d\tau$ compared to $d\sigma_T/d\tau$. This turns out not to be the case. In both Q^2 range, $\frac{dG_M}{dQ^2}$ is independent of τ, reinforcing the earlier conclusion about the suppression of the large-size configurations in the transversely polarized photon.

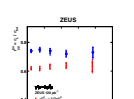

Figure 21

12 Effective Pomeron trajectory

An effective Pomeron trajectory can be determined from exclusive J/ψ electroproduction by using Eq. (2). Since the W dependence of the proton-dissociative contribution was established to be the same as the exclusive J/ψ sample, no subtraction for proton-dissociative events was performed.

A study of the W dependence of the differential $dt/|t|$ cross section as fixed t results in values of $\alpha_{I\!P}(t)$, listed in Table 10 and displayed in Fig. 22, for $Q^2 = 3$ GeV^2 (upper panel) and 10 GeV^2 (lower plot). A linear fit of the form of Eq. (1), shown in the figures, yields values of $\alpha_{I\!P}(0)$ and $\alpha'_{I\!P}$ shown in Fig. 23, and listed in Table 11. The value of $\alpha_{I\!P}(0)$ increases slightly with Q^2, while the value of $\alpha'_{I\!P}$ is Q^2 independent, within the measurement uncertainties. Its value tends to be lower than that of the soft Pomeron [56].

An alternative way of measuring the slope of the Pomeron trajectory is to study the W dependence of the t-slope, for fixed Q^2 values. Figure 24 displays the values of b as a function of W for two Q^2 intervals (see also Table 12). The curves are a result of fitting the data to the expression $b = b_0 + 4\,\alpha'_{I\!P}\,\ln(W/W_0)$. The resulting slopes of the trajectory are $\alpha'_{I\!P} = 0.15 \pm 0.04\,(\text{stat.})^{+0.06}_{-0.04}\,(\text{syst.})$ for $<Q^2> = 3.5$ GeV^2 and $\alpha'_{I\!P} = 0.04 \pm 0.06\,(\text{stat.})^{+0.07}_{-0.04}\,(\text{syst.})$ for $<Q^2> = 11$ GeV^2. These results are consistent with those presented in Table 11.

13 Comparison to models

In this section, predictions from several pQCD-inspired models are compared to the measurements.

Table 10: The values of the effective Pomeron trajectory, $\alpha_{I\!P}(t)$ as a function of $|t|$, for two Q^2 values. The first uncertainty is statistical, the second systematic.

Q^2 low (GeV^2)	Q^2 (GeV^2)	$\|t\|$(GeV^2)	$\alpha_{I\!P}(t)$
2.5	3	0.06	$1.094 \pm 0.014^{+0.010}_{-0.008}$
2.5	3	0.14	$1.059 \pm 0.014^{+0.010}_{-0.008}$
2.5	3	0.28	$1.048 \pm 0.014^{+0.010}_{-0.008}$
2.5	3	0.57	$1.013 \pm 0.022^{+0.010}_{-0.008}$
5.03	10	0.06	$1.149 \pm 0.012^{+0.010}_{-0.008}$
5.03	10	0.14	$1.139 \pm 0.014^{+0.010}_{-0.008}$
5.03	10	0.35	$1.126 \pm 0.021^{+0.010}_{-0.008}$

5-50	10	$1.152 \pm 0.017^{+0.035}_{-0.028}$	$0.114 \pm 0.042^{+0.032}_{-0.040}$

13.1 The models

All models are based on the dipole representation of the virtual photon, in which the photon first fluctuates into a $q\bar{q}$ pair (the colour dipole), which then interacts with the proton to produce the p'. The ingredients necessary in such calculations are the virtual-photon wave-function, the dipole-proton cross section, and the p' wave-function. The photon wave-function is known from QED. The models differ in the treatment of the dipole-proton cross section and the assumed p' wave-function.

The models of Frankfurt, Koepf and Strikman (FKS) [57, 58] and of Martin, Ryskin and Teubner (MRT) [59,60] are based on two-gluon exchange as the dominant mechanism for the dipole-proton interaction. The gluon distributions are derived from inclusive measurements of the pro-

Figure 24

0.0	90	$4.0 \pm 0.2^{+0.5}_{-0.4}$
0.0	97	$4.0 \pm 0.1^{+0.5}_{-0.4}$
0.0	82	$4.6 \pm 0.2^{+0.5}_{-0.4}$
0.0	187	$4.9 \pm 0.3^{+0.5}_{-0.4}$
0.0	134	$7.0 \pm 0.2^{+0.5}_{-0.4}$
0.0	38	$5.8 \pm 0.1^{+0.5}_{-0.4}$
0.0	57	$5.8 \pm 0.2^{+0.5}_{-0.4}$
0.0	82	$5.7 \pm 0.2^{+0.5}_{-0.4}$
0.0	187	$5.9 \pm 0.4^{+0.5}_{-0.4}$
0.0	134	$6.1 \pm 0.2^{+0.5}_{-0.4}$

ton structure function. In the FKS model, a three-dimensional Gaussian is assumed for the ρ^0 wave-function, while MRT use parton-hadron duality and normalise the calculations to the data. For the comparison with the present measurements the MRST99 [63] and CTEQ6c [64] [65] parameterizations for the gluon density were used.

Kowalski, Motyka and Watt (KMW) [63] use an improved version of the saturation model [64-65], with an explicit dependence on the impact parameter and DGLAP [66-69] evolution in Q^2, introduced through the unintegrated gluon distributions [70]. Ivanov, Sandapen and Shaw (ISS) [71] model the dipole-proton interaction through the exchange of a soft [56] and a hard [72] Pomeron, with βad and without (None) saturation, and use fits DGKP and Gaussian ρ^0 wave-functions. In the model of Donch and Fenteis (DH) [73], the dipole cross section is calculated using Wilson loops, making use of the stochastic vacuum model for the non-perturbative QCD contribution.

While the calculations based on two-gluon exchange are limited to relatively high-Q^2 values (typically ~ 4 GeV^2), those based on modelling the dipole cross section incorporate both the perturbative and non-perturbative aspects of ρ^0 production.

13.2 Comparison with data

The different predictions discussed above are compared to the Q^2 dependence of the cross section in Fig. 25. None of the models gives a good description of the data over the full kinematic range of the measurement. The ISS model with the three-dimensional Gaussian ρ^0 wave-function describes the low-Q^2 data very well, while the KMW and DF models describe the $Q^2 \geq 1$ GeV^2 region well.

The various predictions are also compared with the W dependence of the cross section, for different Q^2 values, in Fig. 26. Here again, none of the models reproduces the magnitude of the cross section measure ments. The closest to the data, in shape and magnitude, are the MRT model with

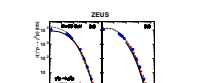

Figure 25
The Q^2 dependence of the $e^+p \to e^+X$ cross section at $W = 300$ GeV. The same data are plotted in (a) and (b), compared to different models, as described in the text. The predictions are plotted in the range as provided by the authors.

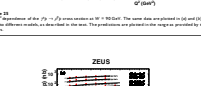

Figure 26
The W dependence of the $e^+p \to e^+X$ cross section for different values of Q^2, as indicated in the figure. The same data are plotted in (a) and (b), compared to different models, as described in the text. The predictions are plotted in the range as provided by the authors.

the CTEQ6.5M parametrisation of the gluon distribution in the proton and the KMW model. The KMW model gives a good description of the Q^2 dependence of $\mathcal{R}$ as shown in Fig. 27.

The dependence of b on Q^2 is given only in the FKS and the KMW models as shown in Fig. 28. The FKS expectations are somewhat closer to the data.

The expected Q^2 dependence of $C_{\rm SW}^{\rm DP}$ is compared to the measurements in Fig. 29. The MRT prediction, using the CTEQ6.5M gluon density, is the only prediction which describes the data in the whole Q^2 range. While all the models exhibit a mild dependence of $C_{\rm SW}^{\rm DP}$ on W, consistent with the data as shown in Figs. 30 and 31, none of them reproduces correctly the magnitude of $C_{\rm SW}^{\rm DP}$ in all the Q^2 bins.

In summary, none of the models considered above is able to describe all the features of the data presented in this paper. The high precision of the measurements can be used to refine models for exclusive ρ^0 electroproduction.

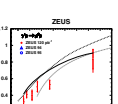

Figure 27

14 Summary and Conclusion

Exclusive J/ψ electroproduction has been studied by ZEUS at HERA in the range $2 < Q^2 < 160\ GeV^2$ and $32 < W < 180\ GeV$ with a high statistics sample. The Q^2 dependence of the $\gamma^* p \to J/\psi p$ cross section is a steeply falling function of Q^2. The cross section moreover with W and its logarithmic derivative in W increases with increasing Q^2. The exponential slope of the t distribution decreases with increasing Q^2 and levels off at about $b = 5\ GeV^{-2}$. The decay angular distributions of the J/ψ indicate s-channel helicity breaking. The ratio of cross sections induced by longitudinally and transversely polarised virtual photons increases with Q^2, but is independent of W and of $|t|$, suggesting suppression of large-size configurations of the transversely polarised photon. The effective Pomeron trajectory, averaged over the full Q^2 range, has a larger intercept and a smaller slope than those extracted from soft interactions. All these features are compatible with expectations of perturbative QCD. However, none of the available models which have been compared to the measurements is able to reproduce all the features of the data.

Acknowledgements

It is a pleasure to thank the DESY Directorate for their strong support and encouragement. The remarkable achievements of the HERA machine group were essential for the successful completion of this work and are greatly appreciated. The design, construction and installation of the ZEUS detector has been made possible by the efforts of many people who are not listed as authors. We thank K Ferrera, J. Kretzschmar, H. Spiesberger, T. Teubner and G. Watt, for providing the results of their calculations.
